BATTERY-BASED SECURED STORAGE BINDING SYSTEM

BACKGROUND OF THE INVENTION

1. Technical Field:

The present invention relates in general to data processing systems, and in particular to data security within such systems. More particularly, the present invention relates to an apparatus and method for logically binding data to a fixed location within a data processing system.

2. Description of the Related Art:

Computer security encompasses a number of different aspects, from passwords and permissions, to data encryption, virus protection, firewalls, and VPNs, software bugs, data backup and physical system security. The continued growth in electronic communication and commerce over expansive computer-driven networks has resulted in a dramatic proliferation of potential security data security problems as data is stored and delivered over multiple networked devices.

Specialized security hardware that complements transmission-based security has been developed to address the myriad of potential security threats to stored and/or transmitted digital data. Such complementary hardware security addresses hardening and assuring the integrity of the environment in which digital application data resides. This security hardware can be utilized for a number of purposes including securing storage of confidential information such as security keys, and off-loading of intensive security operations such as Secure Socket Layer (SSL) processing or digital signature operations. So called “smart cards” and hardware tokens are among the most common forms of secured hardware storage. These mechanisms are tamper-resistant, preventing unauthorized access to security keys. Hardware security devices can also perform cryptographic operations solely from within a system thus providing both a secure environment to access of confidential data, as well as being able to off-load processor intensive operations from network devices.

One such hardware security device is known as an embedded security system (ESS), which provides system security measures outside the interactive processing environment (i.e. the operating system). As depicted in **FIG. 1**, an ESS **102** is typically an integrated circuit chip that is permanently coupled (typically soldered) to a planar (e.g. a motherboard) **104** within a data processing system **100**. Preferably, ESS **102** is uniquely associated with planar **104** such that ESS **102** is not transferrable to another planar. To this end, one function of ESS **102** is to verify the identity of its host planar **104**.

ESS security is not universally required and implementation with all data processing systems, particularly personal computers (PCs), personal data assistants (PDAs), poses additional unnecessary overhead costs to low profit margin products. A possible solution is to provide a removable installation site for optional ESS devices. While this approach provides greater flexibility for customers, it poses an unacceptable security risk for applications, such as public/private key transactions, in which specific data must be

associated with a particular data processing system with absolute assurance.

Referring back to **FIG. 1**, another problem with conventional ESS security is that it provides a relatively inadequate barrier for assuring that sensitive data is uniquely associated with a particular data processing system. As explained above, ESS **102** is typically soldered onto planar **104**. ESS **102** can potentially be desoldered and removed from planar **104**, and installed onto another data processing system, thus compromising the security of data within ESS **102** particularly as this security depends on the need for the object data to be uniquely associated with data processing system **100**.

From the foregoing, it can be appreciated that a need exists for a system that will ensure the status of data as being associated with a particular data processing platform. The present invention addresses such a need by providing a logical binding mechanism that avoids the aforementioned problems associated with physical binding mechanisms.

SUMMARY OF THE INVENTION

5 An apparatus and method for exclusively binding data to a data processing system are disclosed herein. The logical binding apparatus of the present invention includes a detachable circuit device mounted within a system planar. Data to be bound within the system planar is stored in a memory device within the detachable circuit device. A battery signal is applied from the system planar to a binding pin on the detachable circuit device, wherein the binding pin is applied to the input of a binding latch. The binding latch remains in a reset state while the battery signal is applied. Upon removal of said binding signal from the binding pin, the binding latch is set thus signaling a processing unit within the detachable circuit device to remove the data from the memory device.

All objects, features, and advantages of the present invention will become apparent in the following detailed written description.

BRIEF DESCRIPTION OF THE DRAWINGS

The novel features believed characteristic of the invention are set forth in the appended claims. The invention itself however, as well as a preferred mode of use, further
5 objects and advantages thereof, will best be understood by reference to the following detailed description of an illustrative embodiment when read in conjunction with the accompanying drawings, wherein:

FIG. 1 is a block diagram depicting a conventional hardware security system implemented within a data processing system;

FIG. 2 is a block diagram illustrating a battery-based data security apparatus as may be implemented in a preferred embodiment of the present invention; and

FIG. 3 is a high-level flow diagram depicting steps performed for implementing and utilizing the logical binding apparatus depicted in **FIG. 2** in accordance with a preferred embodiment of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

This invention is described in a preferred embodiment in the following description with reference to the figures. While this invention is described in terms of the best mode for achieving this invention's objectives, it will be appreciated by those skilled in the art that variations may be accomplished in view of these teachings without deviating from the spirit or scope of the present invention.

As described with reference to **Figures 2-3**, the present invention provides a hardware security means by which data is logically bound to a particular subsystem of a data processing system. The logical binding means of the present invention is particularly useful within the context of a computer network in which it may be important to ensure that particularly sensitive data is uniquely maintained in only one location within the network (i.e. within one designated data processing system).

One such context in which the need for hardware data security arises is in the development and improvement of security key technologies. As part of the security management employed by credit card companies, for example, public/private security key encryption systems are often utilized. Public/private key encryption allows a vendor (a credit card company, for example) to remotely install a private key into a designated user system module in a manner that the vendor is assured that any information intended for the private use of the user is secure.

Implementation of public/private key security systems requires user-side hardware security. The Trusted Computing Platform Alliance (TCPA) is an industry consortium dedicated to improving trust and security on computing platforms. International Business Machines, Inc. (IBM) is included among the companies that founded and continue to develop

TCPA specifications and guidelines. The current TCPA specification defines a subsystem so that it may be trusted to interactively operate with other systems in a pre-defined manner. The subsystem includes an isolated computing engine whose processes can be trusted because they cannot be altered locally or via network intrusion. One such security subsystem developed in accordance with TCPA guidelines is known as a Trusted Platform Management (TPM) module. The preferred embodiments of the present invention are described herein in **Figures 2** and **3** in the context of a data processing system employing a TPM. However, one skilled in the art will understand and appreciate that the underlying principles depicted and explained with reference to **Figures 2** and **3** are more generally applicable to any application in which there exists a need to bind data to a particular, fixed system location.

With reference now to **FIG. 2**, there is depicted a block diagram illustrating a battery-based data security apparatus as may be implemented in a preferred embodiment of the present invention. Specifically, a logical binding apparatus **200** is shown that is implemented within a system planar **202** (e.g. a motherboard), which may be utilized within any type of data processing system. As explained below and with reference to **FIG. 3**, logical binding apparatus **200** is utilized to exclusively bind data to the data processing system (not depicted) in which logical binding apparatus is employed.

As illustrated in **FIG. 2**, logical binding apparatus **200** includes system planar **202** in which a detachable TPM module card **204** is mounted. A memory device **206** and a processing unit **210** are included within TPM module card **204** to provide a secure interactive data repository in which, for example, private security key data may be established and maintained within the host data processing platform. In accordance with a preferred embodiment, the secure data stored within non-volatile memory device **206** may be received from a remote system, such as a network server (not depicted). Processing unit **210** performs requisite data processing functions required for private key establishment and maintenance.

The specifics of private key encryption and decryption are well known in the art and are not discussed herein.

As further depicted in **FIG. 2**, detachable card **204** further includes a non-volatile storage device, referred to hereinafter as binding latch **208**. Processing unit **210** is communicatively coupled with binding latch **208** such that processing unit **210** can determine the logic state (i.e. set or reset) of binding latch **208**. As an important feature of the present invention, TPM module card **204** is designed and installed within system planar **202** such that a predesignated binding pin **211** is coupled to the input of binding latch **208**.

Although not explicitly illustrated in **FIG. 2**, a system power supply is utilized to provide power for the operation of circuit components mounted onboard system planar **202**. Such system power is typically provided from a host power supply that may be activated and deactivated as determined by a user. In accordance with the depicted embodiment, an alternate dc voltage supply is provided within system planar **202** that provides a constant dc supply independent of the system power supply. Within logical binding apparatus **200**, the alternate dc voltage is provided by a battery **215** that is installed within system planar **202**.

As further depicted in **FIG. 2**, battery **215** is coupled to binding pin **211** such that a constant dc voltage level is provided to the input of binding latch **208**. In accordance with the depicted embodiment, binding latch **208** remains reset (to a logic low, for example) while the dc voltage level from battery **215** remains at binding pin **211**. Binding latch **208** is further designed such that in response to an interruption of the battery signal at binding pin **211**, the logic state binding latch **208** is set (to a logic high, for example). A removal of detachable TPM module **204** would, for example, result in such an interruption resulting in binding latch **208** being set.

As part of the hardware security provided by logical binding apparatus **200**, processing unit **210** continuously monitors the state (i.e. set or reset) of binding latch **208**. Processing unit **210** is programmed to recognize that while binding latch **208** is reset, the security of data stored within non-volatile memory device **206** is assured, and normal processing and maintenance of the data continues. However, in response to detecting that the state of binding latch **208** has changed (i.e. has been set), processing unit commences removing the data stored within non-volatile memory device **206**. If, as in the depicted embodiment, processing unit **210** requires a system power supply to operate, the removal of the data content of non-volatile memory device **206** cannot be immediately performed in response to a physical extraction of detachable TPM module **204** from system planar **202**. Therefore, in the case that the interruption the battery signal and subsequent setting of binding latch **208** is caused by an event resulting in a loss of power to processing unit **210**, the removal of data from non-volatile memory **206** is not performed until detachable TPM module **204** is subsequently installed into system planar **202** or another suitable mounting site. Logical binding apparatus **200**, thus ensures that data stored within TPM module **204** is exclusively and continuously bound to a particular mounting site within system planar **202**.

Although the foregoing description describes binding latch **208** as a non-volatile memory unit, in an alternate embodiment, a volatile memory storage unit (e.g. a flip flop) may be implemented as the binding latch within detachable TPM module **204**. If binding latch **208** is implemented as a volatile memory storage unit, the “set” state of binding latch **208** may be triggered and maintained using a charge pump **207**. In this manner, the set state is maintained until detachable TPM module is subsequently installed, thus allowing processing unit **210** to correctly determine that the data within non-volatile memory device **206** is to be removed.

As an alternative to utilizing charge pump 207 to maintain the “set” binding latch state, processing unit 210 can be programmed to interpret a logic low as the set state of binding latch 208. In such a case, a delay device 212 may be incorporated within the battery signal line between battery 215 and binding pin 211 such that upon a subsequent installation of detachable TPM module 204, the resetting battery signal is delayed long enough for processing unit to have detected the logic low set state and to remove the data from non-volatile memory unit 206 in response.

As described with reference to FIG. 2, the logical binding apparatus of the present invention may be advantageously applied to subsystems developed under guidelines set forth by the TCPA, and more specifically to protection of data stored on a TPM. However, the principles underlying logical binding technique disclosed herein are more widely applicable to subsystems designed to operate at a single physical location within a network environment.

With reference to FIG. 3, there is illustrated a high-level flow diagram depicting steps performed for implementing and utilizing the logical binding apparatus depicted in FIG. 2 in accordance with a preferred embodiment of the present invention. The logical data binding process begins as shown at step 302 and proceeds to step 304 with the original installation of a detachable medium (e.g. detachable TPM module 204) into a system planar (e.g. system planar 202). Proceeding to step 306, the battery signal, V_{bat} , is applied through a signal line from battery 215 within system planar 202 to binding pin 211 on detachable TPM module 204. When detachable TPM module is originally installed and V_{bat} applied to binding pin 211, bind latch 208 is maintained in a reset state as depicted at step 308.

Proceeding to step 310, data, in the form of security keys or otherwise, is stored within non-volatile memory unit 206 as part of the normal operations of detachable TPM

module **204**. During such operation, and as depicted at step **312**, a continuous determination is made of whether or not V_{bat} has been interrupted. This determination is made on a continuous basis in accordance with the design of binding latch **208** which is designed to switch states (from reset to set) in response to removal of V_{bat} from its input at binding pin **211**.

As illustrated at step **314**, in response to a removal of V_{bat} from binding pin **211**, binding latch **208** set. Next, processing unit **210** detects the setting of binding latch **208** and removes the data from nonvolatile memory unit **206** as depicted at steps **316** and **318**. After the secure data has been removed, the logical binding process terminates as shown at step **320**.

A method and system have been disclosed for logically binding data to a hardware platform. Although the present invention has been described in accordance with the embodiments shown, one of ordinary skill in the art will readily recognize that there could be variations to the embodiments and those variations would be within the spirit and scope of the present invention. Accordingly, many modifications may be made by one of ordinary skill in the art without departing from the spirit and scope of the appended claims.
